## Introduction

The most important challenge of the European forestry is a sustainable farming with both the feasible wood production and encouragement of non-production functions of forest including biodiversity (LINDENMAYER ET AL. 2000). The majority of virginal forests in submontane and montane areas of the central Europe was cutted down and changed on the spruce monocultures (RÖHLE 1991; PRETZCH 1996; VACEK ET AL. 2009). These even-aged stands have the high productivity but they are very sensitive to weather conditions (especially wind storms) and insects outbreaks (ROTHER ET BORCHERT 2003).

In forests, competition between humans and saproxylic beetles has a long history (GROVE 2002). The European spruce bark beetle *Ips typographus* is considered to be the most serious pest species of mature spruce stands, mainly of Norway spruce (*Picea abies*), throughout Eurasia (GRODZKI ET AL. 2004; WERMELINGER 2004). Among all types of forest damage from 1950 to 2000 in Europe, 2–9 million m<sup>3</sup> of timber per year were destroyed by bark beetles, mainly *I. typographus* (SCHELHAAS ET AL. 2003).

The preference of this species for mature spruce trees increases the economic impact of its damage. With regard to these facts, it is not surprising that most published research on bark beetles deals with damage and prevention of outbreaks in commercial forests (ERIKSSON ET AL. 2006; HEDGREN ET SCHROEDER 2004; REEVE 1997; WERMELINGER 2004). By contrast, some studies have pointed out the ecological value of *I. typographus* and other bark beetles as ecosystem engineers and so-called keystone species, driving forest regeneration, and producing snags and a rich patchiness in forest canopies (JONÁŠOVÁ ET PRACH 2004; MARTIKAINEN ET AL. 1999; MÜLLER ET AL. 2008). Apart from providing these ecosystem services, the arthropod complex associated with *I. typographus*, including more than 140 species (WESLIEN 1992), is in itself a significant contribution to diversity. BOHÁČ ET MATĚJKA (2009) approved that the diversity of epigeic and hemiedaphic beetles in the southern Šumava (Plechý Mt. region) is much higher in the dead tree stand with coarse woody debris in comparison with clear-cut areas with removed wood.

The assessment of the habitat preference of species and differences of beetle communities on plots in the different stage of forest decline, this study addressed the following questions:

1. Does species activity and diversity alter on the plots with the different stage of decline?
2. Do preferences of species for plots with the different stages of spruce forest decline support the hypothesis that the keeping of dead tree stand on plots after bark beetle outbreak is better for biodiversity conservation than the cutting down of trees and the abolishment of stems?

## Material and methods

### Experimental plots

Ten plots were studied in the vicinity of Modrava in the National Nature Park Šumava. The characteristics of studied plots are described in the Table 1. All plots are very similar concerning all characteristics with exception of the past management and the stage of the spruce forest decline. We can designate three groups of experimental plots after the stage of the forest decline:

1. Group L - plots with actually living mature trees; many trees are currently invaded by bark beetle - see development of the individual plots in MATĚJKA (2010a).
2. Group D - plots with dead tree stand, wood is remaining in the ecosystem.
3. Group C - plots with damaged stands, which were clear-cut.

### Sampling of beetles

The method of pitfall trapping was used for the collection of epigeic beetles. A row of five plastic pitfall traps (diameter 7 cm) was exposed in each locality from 20<sup>th</sup> June to 21<sup>st</sup> October 2010. Pitfall traps were filled with a mixture of ethylenglykol. The material from the traps was collected every month. The material was transported to the laboratory for the next processing and determination.

The degree of human impact was studied by finding of frequency of species of different ecological groups (HŮRKA ET AL. 1996; BOHÁČ 1999; BOHÁČ ET AL. 2008). The species were divided into groups as follows:

- Group r (relic species) includes species remaining from communities of past period, e.g. species with arcto-alpine, boreomontane and boreo-alpine occurrence, inhabiting mainly mountains and peatbogs, or only occurring in remains of forests stands, which because of their high species diversity resemble recent climax forests.
- Group a (adaptable species) encompasses species of both natural and managed forests.
- Group e (generalists or ubiquitous species) comprises eurytopic species that successfully occupy deforested sites and are also found in areas strongly affected by man.

The method of ecological analysis of beetle communities (BOHÁČ 1999) was used for evaluating of community structure particularly. Frequency of ecological groups according to their relation to the naturalness of biotopes, preference of screened or opened habitats (or living in both) and hygropreference were used during this analysis. Increased influence of man was found to bring about an increase in the frequency of eurytopic species, species preferring opened habitats and species with lower moisture preferences.

## Statistical analysis

Data were stored in the database DBreleve (MATĚJKA 2009). The basic processing of the data was made in this program. Data of the species activity (number of caught individuals in 5 traps in the plot) from all months of sampling were summed for basic description of the investigated beetle communities. Species richness (number of all species, S), total species diversity as the Shannon-Wiener's index (H) and equitability (e) were calculated in the DBreleve.

The Ward's method of hierarchical agglomerative classification (WARD 1963) with Euclidean distance was employed for differentiation of the communities on the plots. Species data for this analyze were represented by logarithm-transformed activities [ $\log(x+1)$ ].

The single-factor ANOVA was used to statistical testing of differences in structural parameters (e.g. species richness and diversity) among distinguished groups of the plots.

## Results and discussion

### Plots preferences (number of species and its activity)

The number of species found in all studied plots was 89. The number of occurred species was different in studied plots (Table 2). The highest number of species was found in clear-cut areas (plots a0, ap2 and p2) - 34 to 36 species. The lower number of species (25) was occurred on clear-cut area and with the small rest of laying trees (M6) and on the plot with declining trees (M3). The lowest number of species was found on the plots with the living forest particularly invaded by bark beetle. This fact is caused by the fact that the clear-cut plots are invaded by ubiquitous and anthropotolerant species with good migration possibilities. These species are adapted to habitats without trees and are able to leave even in the habitats with very sparse or without vegetation (e.g. *Amara aenea*, *Poecilus versicolor*, *Bembidion lampros*, *Phyllotreta nemorum*, *Omalium caesum*, *O. rivulare*, *Byrrhus pilula*).

Species living in the forest even under the bark beetle attack are often stenotopic and adapted to the forest microclimate (higher humidity and low average temperature). These species are very sensitive to great difference in the daily changes of microclimate (*Othius myrmecophilus*, *Pterostichus burmeisteri*, *Dinaraea aequata*, *Abax ovalis*, *Carabus auronitens*, *C. linnaei*, *C. sylvestris*, *Anthobium melanocephalum*, *Domene scabricollis*, *Trechus pulchellus*, *Leptusa pulchella*, *Quedius plagiatus*).

### Classification of the studied plots

Classification of beetle communities on the studied plots (Fig. 1) shows two main groups of the plots. It is clear that the clear-cut plots with removed wood are situated in the separated cluster A. Experimental plots with living trees (L) and with declined stands are situated in the second cluster B.

Number of species, activity and the total species diversity are higher on the plots of the group A (Figs. 2-5). This fact is caused by the higher activity of eurytopic species which are able quickly occupy deforested areas. Some forest species are still able to survive on these plots. The equitability of beetle communities is higher on plots with living forest or forest with different stage of decline on the other site.

### Distribution of ecological groups of beetles on studied plots

The species can be separated into three groups after their presence or absence in the plots representing classification groups A and B (Table 2).

Species typical for the first classification group A (species group 1 in table 2) can be identified as r-strategists after PIANKA (1970). These species are indicated as eurytopic species that successfully occupy deforested sites and are also found in areas strongly affected by man. The surprise is the presence of relic species *Eucnecosum brachypterum*. This species prefer montane meadows, stony debris, snow fields and plots affected by avalanches. It is possible that plots with fresh and dead trees is suitable for this species.

Species typical for the classification group B (species group 3 in table 2) covers with ones of the narrower ecological valency. This group includes all three ecological groups after BOHÁČ (1999) and HŮRKA ET AL. (1996). The minority represents very rare montane species (2 species). Staphylinid beetle *Atrecus longiceps* (Fig. 6) is named as indicators of rests of virginal montane forests (MÜLLER ET AL. 2005). The majority of this beetle species belongs to the group of adaptable species living both in natural and managed forests. Small portion of species belongs to eurytopic species (previous group). These species are adapted to living in decaying substances (*Dinaraea aequata*), phytophagous species with good flying possibilities migrated to forest from cutovers (*Phyllobius calcaratus*) or living in dead wood (*Hylastes cunicularius*)

Neutral species (species group 2 in table 2) cover different preference of habitats. Some relic montane species were found preferred montane meadows (*Bryoporus rufus*). The proportion of eurytopic species and adaptable species is approximately similar.

### Seasonal dynamics of the beetle community

Changes of total epigeic beetle activity during year 2010 (Fig. 6) shows the highest activity in June and July. The activity is decreasing from July to September rapidly. The small elevation was observed during the October. The similar character of the dynamics we can see by the monitoring of the changes of epigeic beetle species richness (Fig. 7) and changes of epigeic beetle total species diversity (Shannon-Wiener's index) during year (Fig. 8).

### Summary

Communities of epigeic beetles were studied on 10 plots with the different stage of decline and clear-cut plots without coarse woody debris. The species diversity and activity differs on glades without trees and coarse woody debris. The study of beetle communities support the hypothesis that the keeping of dead tree stands on plots after bark beetle outbreak is better for biodiversity conservation than the cutting down of trees and the abolishment of stems.

<i>Dexiogyra corticina</i> (Erichson, 1837)	a	s										2
<i>Hylobius abietis</i> (Linnaeus, 1758)	a	s										2
<i>Rhizophagus grandis</i> Gyllenhal, 1827	a	s										1

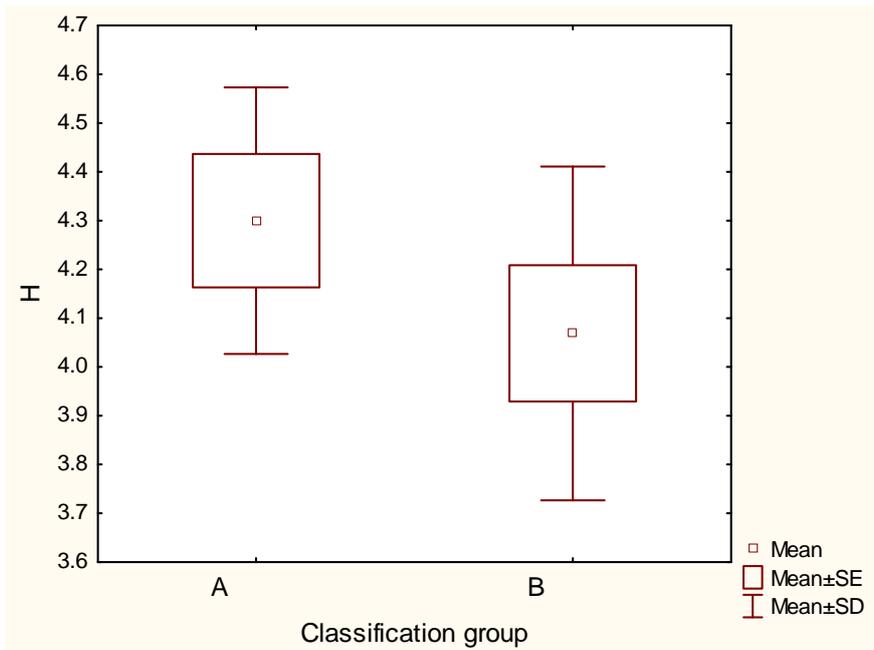

**Fig. 1.** Classification of beetle communities on the studied plots (Ward's method with quadrate of euclidean distance). Transformed data of the activity (number of specimen) in pitfall traps in all months (Juni-October) were used.

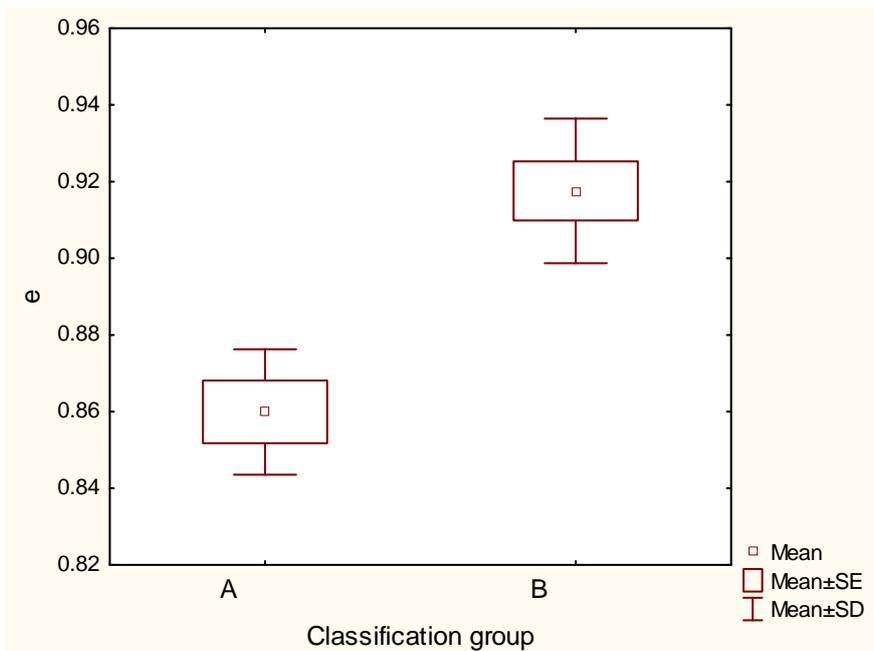

**Fig. 2.** Species richness according to two classification groups. Values are different on level  $p=0.017$  (ANOVA test).

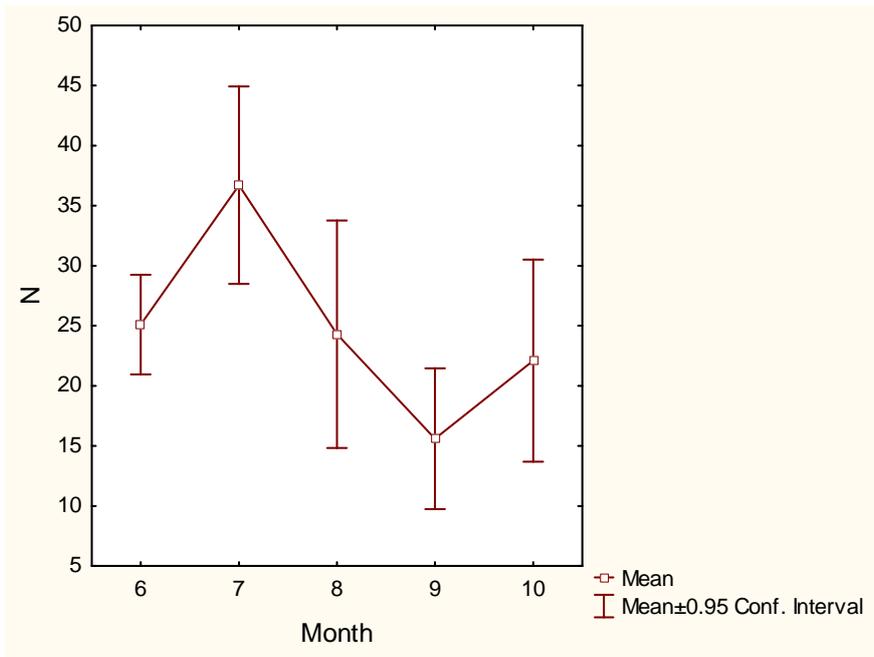

**Fig. 3.** Number of individuals according to two classification groups. Values are different on level  $p=0.002$  (ANOVA test).

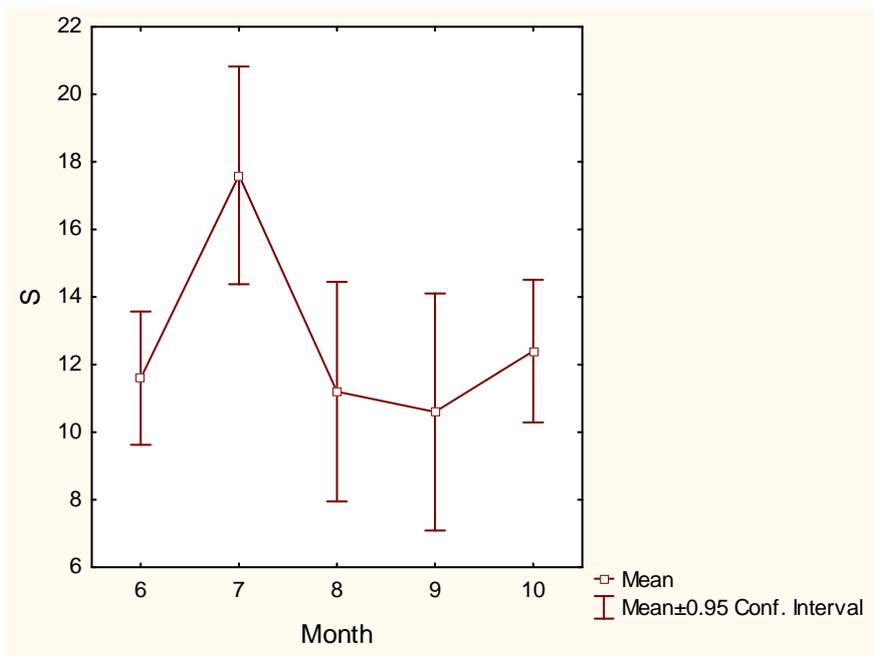

**Fig. 4.** Shannon-Wiener's index of species diversity according to two classification groups. Values are not statistically different (ANOVA,  $p=0.29$ ).

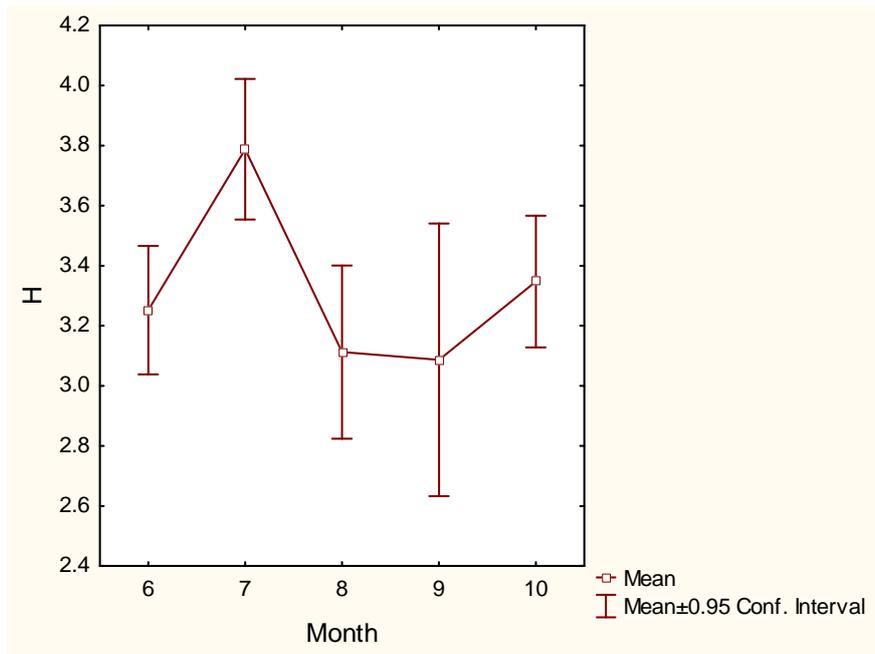

**Fig. 5.** Equitability according to two classification groups. Values are different on level  $p=0.001$  (ANOVA test).

**Fig. 6.** Changes of total epigeic beetle activity during year 2010.

**Fig. 7.** Changes of epigeic beetle species richness during year 2010.

**Fig. 8.** Changes of epigeic beetle total species diversity (Shannon-Wiener's index) during year 2010.
